Problem formulation

Data generator

Model PCA-regression

Motivation

- Realistic data on low-dim. manifold.
- PCA-regression similar in structure to successful encoder-decoder.

Aim: Understand the model generalization in high dimensions.

Pre-training the PCA – Setup

Two step training procedure:

- Pre-training data set $\{\mathbf{x}_i\}_{i=1}^{n_p}$ → unsupervised pre-training of PCA.
- Training data set $\{\mathbf{x}_i, y_i\}_{i=1}^n$ → linear regression on the PCA features $\hat{\mathbf{z}}_i$.

⇒ Setting comparable to pre-training of encoder-decoder models.

For technical reasons: orthogonalize features and noise $\mathbf{x}_i = \mathbf{D}\mathbf{z}_i + \mathbf{D}_\perp \mathbf{e}_i$. Then:

$$\text{Model: } \hat{\mathbf{z}}_i = \hat{\mathbf{V}}^T \mathbf{x}_i$$

$$\text{Data generator: } \mathbf{z}_i = \mathbf{D}^+ (\mathbf{x}_i - \mathbf{D}_\perp \mathbf{e}_i) = \mathbf{D}^+ \mathbf{x}_i$$

Interpretation Correct estimation of true eigenvectors \mathbf{D}^+ with $\hat{\mathbf{V}}$ crucial.

Pre-training – Analysis

Define projection loss: $\mathcal{L}(\mathbf{D}) = \mathbb{E} [\|\mathbf{x}\|_2^2 - \|\mathbf{D}^+ \mathbf{x}\|_2^2]$; $\mathcal{L}(\hat{\mathbf{V}}) = \mathbb{E} [\|\mathbf{x}\|_2^2 - \|\hat{\mathbf{V}}^T \mathbf{x}\|_2^2]$

Theorem Take $t > 0$, $k_j^2 = s_j(s_j + \text{Tr}(\mathbf{C}))$, then

$$P(\mathcal{L}(\hat{\mathbf{V}}) - \mathcal{L}(\mathbf{D}) > t) \leq \frac{4}{tn_p} \left(\sum_{i=1}^{\min(d, \hat{d})} \sum_{j=i+1}^m \frac{k_j^2}{|s_i - s_j|} + \sum_{i=\hat{d}}^d \sum_{j=1}^m \frac{k_j^2 s_i}{(s_i - s_j)^2} + \sum_{i=\hat{d}}^d \sum_{j=1}^m \frac{k_j^2 s_j}{(s_i - s_j)^2} \right)$$

Interpretation Good covariance estimation $\hat{\mathbf{V}}$ if:

- Correct latent dimension chosen, i.e. $\hat{d} = d$.
- Many pre-training samples n_p .
- Quickly decaying eigenvalues, i.e. $|s_i - s_j|$ large.

Connection to risk

- Xu and Hsu [2] present results for risk with general but known $\hat{\mathbf{V}}$.
- Theorem provides missing connection when [2] can be used in practice.

Supervised case – Analysis

Analyze risk on new data: $R(\hat{\boldsymbol{\theta}}) = \mathbb{E}_{y_0} [(y_0 - \hat{y}_0)^2]$

Lemma Sample covariance $\hat{\mathbf{C}} = \frac{1}{n} \mathbf{X}^T \mathbf{X}$ and the true covariance \mathbf{C} . Orthogonal projectors $\boldsymbol{\Pi} = \mathbf{I}_m - \hat{\mathbf{V}} \hat{\mathbf{V}}^T$. Then,

$$\mathbb{E}_\epsilon [R(\hat{\boldsymbol{\theta}})] = \boldsymbol{\beta}^T \boldsymbol{\Pi} \mathbf{C} \boldsymbol{\Pi} \boldsymbol{\beta} + \frac{\sigma_\epsilon^2}{n} \text{Tr}(\hat{\mathbf{V}}^T \hat{\mathbf{C}} \hat{\mathbf{V}} \hat{\mathbf{C}}^+ \hat{\mathbf{V}}) + \sigma_\epsilon^2$$

Compare with Hastie et al. [1] for direct linear regression:

$$\mathbb{E}_\epsilon [R(\hat{\boldsymbol{\theta}})] = \boldsymbol{\beta}^T \boldsymbol{\Pi} \mathbf{C} \boldsymbol{\Pi} \boldsymbol{\beta} + \frac{\sigma_\epsilon^2}{n} \text{Tr}(\mathbf{C} \hat{\mathbf{C}}^+) + \sigma_\epsilon^2 = \text{bias}^2 + \text{variance} + \text{irreducible noise}$$

Interpretation:

- Only variance term differs
- Estimated eigenvectors $\hat{\mathbf{V}}$ project covariance \mathbf{C} into \hat{d} -dimensional subspace → expect no interpolation peak at $\gamma = 1$

Supervised case – Numerical results

Isotropic data

Isotropic setup: Use $n = 400$ samples, $\mathbf{C} = \mathbf{I}_m \rightarrow d = m$.

Interpretation

- Numerical simulation and analytical solution align.
- No interpolation peak at $\gamma = 1$.

Latent variable data with $\alpha = 0$

Latent variable data with $\alpha = 0.25$

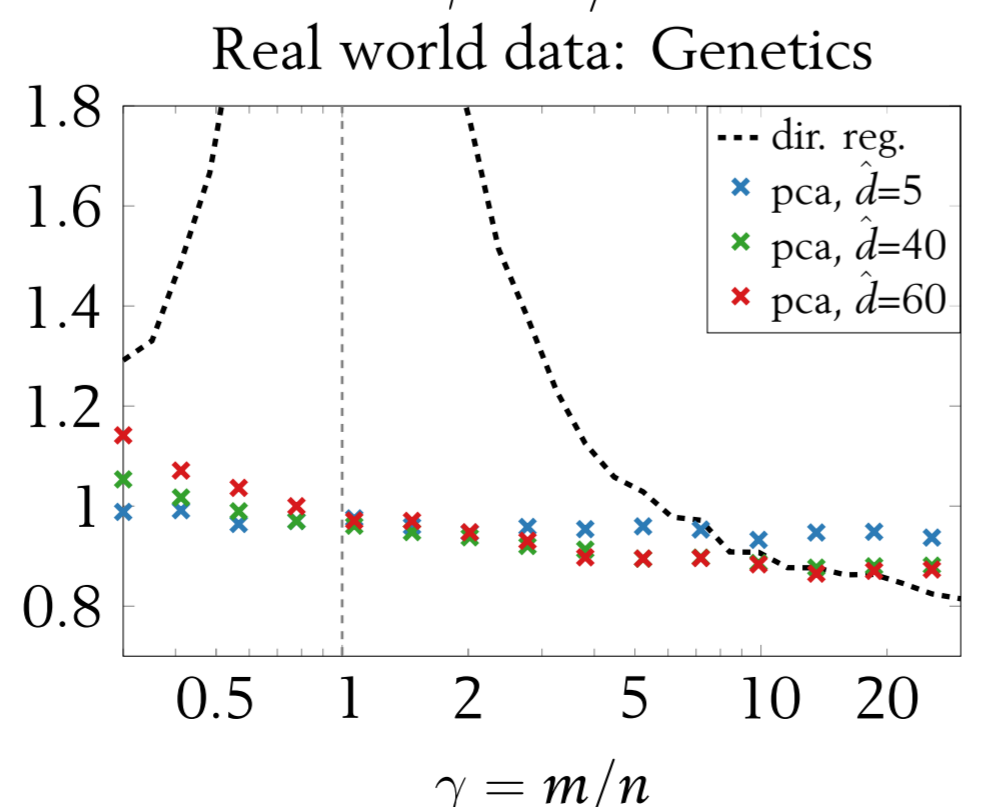

Latent var. setup: $d = 20$, $n = 400$.

Interpretation

- $\hat{d} \geq d \rightarrow$ PCA-regression=dir. reg. for γ large/small.
- $\hat{d} < d \rightarrow$ solution is suboptimal.

Genetics data

- Predict phenotypes from 1.1M genotypes.
- Resemblance to the latent variable results.

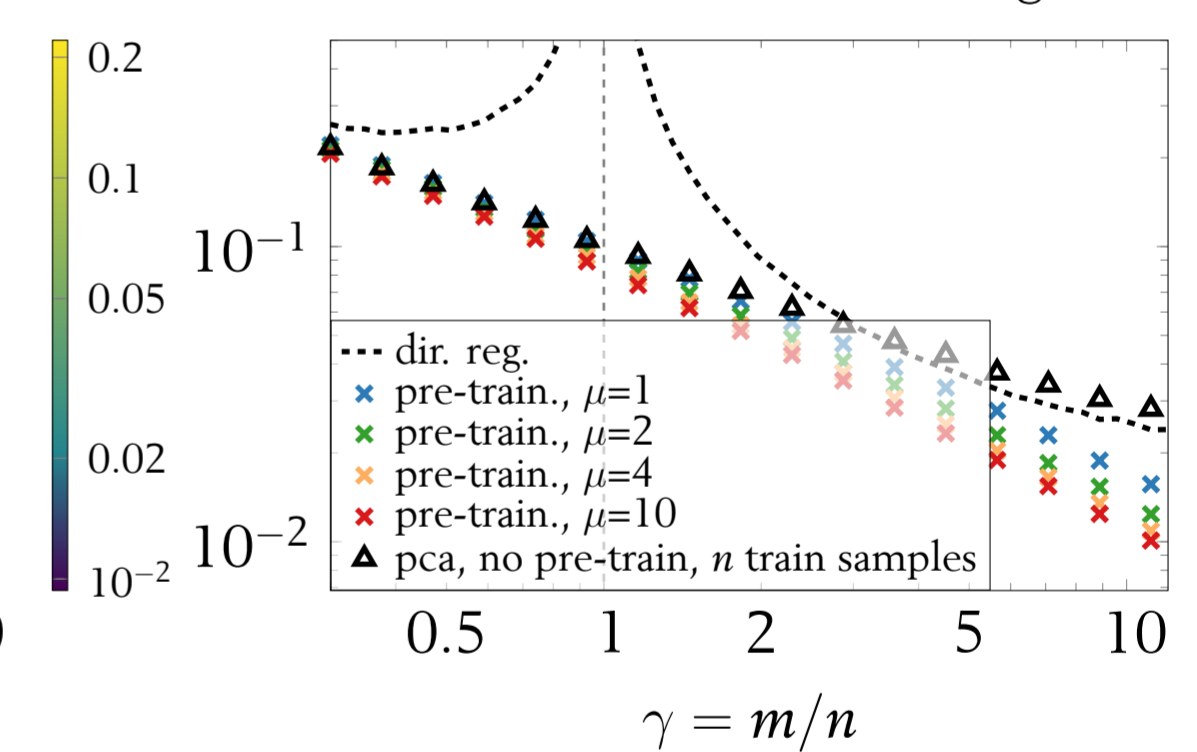

Pre-training – Numerical results

Risk with pre-training, $\alpha = 0.25$

Horizontal slices of left figure

For $\alpha = 0$: more pre-training data n_p does not change risk; horizontal slices equal.

Interpretation

- Risk decreases for increasing γ ; similar to supervised case.
- $\alpha = 0.25$: risk decreases for more pre-training data n_p ; especially for $\gamma > 1$.
→ for $\alpha = 0$ eigenvectors perfectly estimated.
→ for $\alpha = 0.25$ eigenvector estimation improves with more n_p .

Conclusion

Supervised case:

- Generalized results from [1] for PCA-regression.
- Selecting sufficiently large \hat{d} is crucial for low risk.

Pre-training:

- More pre-training data n_p only help to improve eigenvector estimates.
- $\alpha > 0$ is necessary such that more pre-training data are helpful.
